In references [1] [2] Lombardi proposes the "slenderness coefficient":

\[ C = \frac{F^2}{V/H}, \text{ see Fig. 1,} \]

to be used, in conjunction with height H, to judge the susceptibility of an arch dam to cracking, with particular emphasis on shear effects.

Average shear stress along the foundation surface A (A = 2hH (\sqrt{1 + \alpha^2 + \beta^2}), with h = average thickness) is evaluated neglecting the arch action; in fact, consideration of the arch effect would reduce the shear contribution, but since this is certainly not uniform in intensity and direction, one should increase the average to evaluate the local maximum shear. Assuming the two effects to roughly compensate each other, we obtain an effective shear stress of the order of:

\[ \tau = 1.25 \frac{\gamma_s \left( \frac{F^2}{2} \cdot H \cdot H + \frac{F}{2} \cdot \alpha H \cdot H \right)}{2hH \left( \frac{F}{2} + \sqrt{1 + \alpha^2} \right)} \]

\[ = \frac{1.25 \gamma_s}{2} \left( \frac{F}{2} + \alpha \right) \left( \frac{\beta}{2} + \sqrt{1 + \alpha^2} \right) (\alpha + \beta) \text{ (CH)} \]

(taking into account that \( C = \frac{F^2}{V/H} \) and that \( V = Fh \)).

By taking \( \tau_{cr} \leq 3 \) MPa as an upper limit to avoid cracking it comes:

\[ CH \leq 240 \frac{(\alpha + \beta)(\beta + 2\sqrt{1 + \alpha^2})}{\frac{F}{2} + \alpha} \]

(shear criterion)

In the case of Kölberbrun \( \beta = 0.77, \alpha = 1.96, \)

\[ CH \leq 2300. \]

With the dimensions of the dam one gets instead:

(*) The coefficient 1.25 is adopted as an average between 1.5, which would apply for a constant-section beam, and 1 which would more nearly apply in extreme cases, for inclined facings and non-uniform section.
CH = 3500,

definitely larger than the limit.

In the case of Valle di Lei $\beta = 0$, $\alpha = 2$;

CH $\leq$ 2250.

With the dimensions of the dam one gets:

CH = 2500,

only slightly larger.

It is to be noted, however, that the crisis of the structure can take place also for tensile cracking. In this context, let's consider the arch at mid-height. For a dam only 30 m high, ($H = 30$) it would be reasonable to adopt a thickness of $h = \frac{H}{10} = 3$ m. The average compression in that arch would be:

\[
\begin{align*}
\left| \sigma_4 \right| &= \frac{1}{2} \cdot \gamma \cdot \frac{h}{h} \cdot R_4 \quad (*) \\
\left| \sigma_4 \right| &= 3 \text{ MPa.}
\end{align*}
\]

At the abutment intrados we would have $\sigma_{\text{max}} = 0$, $\left| \sigma_{\text{max}} \right| = 2 \sigma_4$.

Now if we take a dam with the same shape, but n times larger, all stresses would increase n times. To leave the stresses roughly unchanged, one would have to increase the thickness more than linearly:

\[ h \rightarrow n \cdot n' \cdot h, \text{ with } x > 0. \]

A heuristic criterion could then run more or less as follows:

At the point of maximum danger for tensile cracking the stress from normal load, $\sigma_4$, should be roughly equal to the stress from bending. If this is assured in the "small" dam:

\[
\sigma_4 = \sigma_4;
\]

in the "large" dam it should then be, thanks to the increase in the ratio $n^{\alpha}$ in thickness:

\[
\frac{n \sigma_4 + n \sigma_4}{n^{\frac{1}{2}} (n')^{\frac{1}{2}}} = \sigma_4 + \sigma_4.
\]

Taking into account (4) it comes:

\[
\frac{n}{(n')^{\frac{1}{2}}} + \frac{n}{n'} = 2.
\]

The solution for $x$, thus depends on the magnification factor, n, but it is readily found that for:

\[
1 \leq n \leq 5
\]

one gets:

\[
\frac{2}{3} \leq x \leq 0.734,
\]

so that one is justified in taking the constant value:

\[
x = 0.7.
\]

With this assumption, scaling up of dimensions ($H$) to a factor $n$ entails scaling up thicknesses to a factor $n^{\alpha}$ in order to maintain roughly the same stress level. Thus the scaling up of $C$ will be to a factor:

\[
C \rightarrow \frac{n^{\alpha} S^4}{n^{\frac{1}{2}} n^{\frac{1}{2}} V H} = n^{\alpha - \frac{3}{2}} C
\]

(slenderness coefficient should be smaller for larger dams).

More specifically, from (3) and Fig. 2, under the assumption of roughly 106° angular aperture of the middle arch, so that:

\[
R_{4G} = \omega \cdot \beta \cdot H_4 \left( \frac{1}{2} + \frac{n}{2} \right)
\]

for the dam 30 m high, of 3 m average thickness, it comes, keeping into account (9):

\[
C < 4662 \left( \alpha + \beta \right)^{0.7} H^{-0.7}
\]

(normal stress criterion)

Thus, to effect a preliminary, rough evaluation of the susceptibility of a dam to cracking, one could suggest the following procedure:

a) from the shape factors $\alpha$, $\beta$ compute the "aspect factors" of the valley:
\[
\begin{align*}
C_1 &= \frac{(\alpha + \beta) (\beta + 2 \sqrt{1 + \alpha^2})}{(\frac{\beta}{2} + \frac{\alpha}{2})} \times 240 \\
C_2 &= (\alpha + \beta)^{-0.1} \times 1550 \\
\end{align*}
\]

(13)

\[\log C = \log C_1 - \log H \text{ for the shear criterion,}\]

\[\log C = \log C_2 - 0.7 \log H \text{ for the normal stress criterion}\]

(14)

(see Fig. 3)

The region of the log-log plane under both these two lines (\(^\ast\)) identifies, for the valley being considered, the dams relatively safe from cracking; all points above should be regarded as at risk from cracking.

It is deemed that the above considerations, while in agreement with the previous work by LOMBARDI, can further refine his criterion, by taking into account the "aspect factors" of the valley (13). Moreover, a physical basis for the statistically found subdivisions of existing dams into "safe regions" and "regions of cracking potential" in the plane (C,H) is provided.

Naturally, other important parameters influencing the cracking potential of arch dams are the ratio of Young moduli of rock and concrete, the angular aperture of arches, etc.

All of these should be taken together and duly considered by the designer in the light of the state of the art knowledge and of the past experience.
